We study the stability of various kinds of graphene samples under soft x-ray irradiation. Our results show that in single-layer exfoliated graphene (a closer analog to two-dimensional material), the in-plane carbon-carbon bonds are unstable under x-ray irradiation, resulting in nanocrystalline structures. As the interaction along the third dimension increases by increasing the number of graphene layers or through the interaction with the substrate (epitaxial graphene), the effect of x-ray irradiation decreases and eventually becomes negligible for graphite and epitaxial graphene. Our results demonstrate the importance of the interaction along the third dimension in stabilizing the long range in-plane carbon-carbon bonding, and suggest the possibility of using x-ray to pattern graphene nanostructures in exfoliated graphene.

The existence and stability of two-dimensional (2D) materials has been a fundamental yet long-debated subject. Graphene, a purely one-atom-thick two-dimensional material formed by carbon atoms arranged in a honeycomb lattice, was previously presumed not to exist because strictly two-dimensional materials are thermodynamically unstable.1–3 The recent discovery of graphene4,5 has raised renewed interest regarding the long-debated issue about the stability of two-dimensional materials. Although it has been proposed recently that the ripples—corrugation along the third dimension in free-standing exfoliated graphene samples help to stabilize graphene,4,6,7 no direct experimental evidence about what causes the stability of the $sp^2$ bonds has been obtained so far. Here we present direct experimental proof that it is indeed the interaction along the third dimension that drives the stability of the graphene sheet. In particular we show that the closer the graphene sample is to a two-dimensional crystal, the easier it is for the $sp^2$ bonds to be broken under soft x-ray irradiation, resulting in nanocrystalline structures. This conclusion was based on a systematic study of various kinds of graphene samples with different amount of interaction along the third dimensionality, including exfoliated graphene on SiO$_2$, suspended exfoliated graphene, and epitaxial graphene on SiC, and by combining two important techniques—x-ray absorption spectroscopy, which is sensitive to the $sp^2$ bonding, and Raman spectroscopy which is sensitive to the edges of the graphene samples.5,8,9 Our results show the direct evidence about the instability of two-dimensional graphene, and points out a possible route of using x-rays to engineer graphene nanoribbons.

The samples studied were exfoliated graphene samples on SiO$_2$/Si and epitaxial graphene on SiC. The thickness of exfoliated graphene samples is characterized by optical contrast11,12 and confirmed by Raman measurements.13,14 The thickness of epitaxial graphene is characterized by low-energy electron microscope (LEEM).15 Although the overall electronic structure of graphene is preserved in both types of graphene samples, the interaction along the third dimension is much stronger in epitaxial graphene than exfoliated graphene. This is manifested by the formation of a first carbon rich layer strongly bonded with the SiC substrate,16 and the opening of a gap in the $\pi$ bands for the first graphene layer.17,18 X-ray absorption spectroscopy (XAS) spectra at the C 1s edge were taken with photonemission electron microscope (PEEM) at PEEM2 of the Advanced Light Source (ALS) in Berkeley. The microscope is operated in the total electron yield (TEY) mode by recording the intensity maps while sweeping the photon energy across the C $K$ edge. The photon flux was cut down to only 1/3 of the regular value to decrease the x-ray radiation damage on the sample. Raman spectra were taken on a commercial system (Renishaw In-Via) at a wavelength of 514 nm (Argon laser). Special care was taken to minimize laser exposure on samples and subsequent spectra at the same spot showed no change. The spatial resolution of both techniques allows easy detection of each graphene region with different thickness.

Figure 1(a) shows the optical image of a typical exfoliated sample. Clear optical contrast can be observed between regions of graphene with different sample thickness.5 Figure 1(b) shows the PEEM image taken at 279 eV photon energy before the C 1s $K$ edge on the same sample. Similar to the optical image [Fig. 1(a)], strong intensity contrasts between different regions are observed in the PEEM image shown in Fig. 1(b). Thicker graphene regions will appear darker in the pre-edge spectra because photoelectrons travel through more materials before being emitted to the vacuum, thus making PEEM another powerful tool to capture the thickness of graphene films. Figure 1(c) shows the C 1s XAS spectra taken on single-layer exfoliated graphene with two different polarizations. The two main features at $\approx$285 eV, and at $\approx$292 eV, correspond, respectively, to the $\pi^*$ orbitals at the $K$ and $M$ points of the Brillouin zone and to the $\sigma^*$ orbitals at the $\Gamma$ point.19 Their in-plane and out-of-plane characters are confirmed by the dependence from the polarization of the incident photons [Fig. 1(c)].19 More specifically, when the light polarization is in-plane, only the in-plane $\sigma^*$ orbital at 292 eV contributes to the C 1s edge, while when the out-of-
plane polarization component increases, the intensity of the $\pi^*$ feature at 285 eV strongly increases.

In Fig. 1(d) we show the C 1s spectra of exfoliated graphene for different sample thickness. As in Fig. 1(c), the $\pi^*$ feature and the splitting of the $\sigma^*$ orbitals are observed in all the spectra, independent of the sample thickness. The main difference is that as the thickness increases, the intensity of the $\sigma^*$ and $\pi^*$ features increases.

The high energy resolution and sample quality of this experiment has enabled us to clearly resolve the splitting of the $\sigma^*$ peaks, not observed in a previous study, and hence to quantify the thickness dependence of the absorption spectra and directly compare it to the optical reflectivity data. In Fig. 1(e) we show the integrated absorption intensity, determined from the area underneath the $\pi^*$ and $\sigma^*$ orbitals near the C K edge. The data clearly show that the intensity of the $\pi^*$ and the $\sigma^*$ orbitals scales linearly with the sample thickness for up to three layers. Interestingly, this is in close analogy to the quantized steps observed in optical reflectivity and transmission for different graphene thicknesses, which are defined only by the fine-structure universal constant $\alpha = e^2/\hbar c$. This result suggests that, even at higher photon energies the universality still holds and the absorption spectra is still related to the universal constant $\alpha$, the parameter that defines the optical transparency of graphene.

The strong radiation-induced change of the single-layer exfoliated graphene [Fig. 2(a)] is in contrast to the almost negligible effect observed on the epitaxial sample [Fig. 2(e)]. As for the exfoliated sample, the two main features in the spectra are the $\pi^*$ and the $\sigma^*$ orbitals, which occur at the same energy, a further confirmation that the overall electronic structure of exfoliated and epitaxial graphene is similar in nature. In this case however, the relative intensity of the $\pi^*$ peak is much weaker, suggesting that the $\pi^*$ derived states are partially occupied. This is likely due to a charge transfer from the buffer layer, in agreement with photomission measurements reporting an highly doped nature of this sample. We note that, although the radiation-induced damage presented here is observed for all the samples studied (more than five samples in total), in some cases the absorption spectra of single-layer graphene shows more dramatic changes. In an extreme case [inset in Fig. 2(a)], the signal of the $\sigma^*$ orbital completely disappeared (pointed to by a gray arrow) and an additional peak arose before the adsorption edge (pointed to by a red arrow), reminiscent of the edge states observed in graphite.

The time dependence of the spectra in Fig. 2(e) clearly shows that the epitaxial sample is very stable and the damage induced by x-ray irradiation is negligible, despite the much longer exposure time. This result is in striking contrast with the strong time dependence observed in the exfoliated sample [Fig. 2(a)]. Note that these two types of samples were measured in the same chamber under the same conditions, and therefore this substantial difference in stability should be attributed to their intrinsic nature, e.g., the different strength of interaction along the third dimension, and not an artifact of the measurements.

To better understand the origin of this radiation-induced
change, we compare Raman measurements on the same samples measured before and after exposure to soft x-rays (see Fig. 3). Before exposure, the exfoliated graphene sample shows a sharp G peak induced by the zone-center $E_{2g}$ phonon at $\approx 1570$ cm$^{-1}$, and a strong 2D peak (overtone of the zone-boundary $A_{1g}$ phonon) at $\approx 2700$ cm$^{-1}$. The 2D peak in single-layer graphene shows a single component, while the 2D peak for bilayer, trilayer graphene and many layer graphite is broader and contains multiple components, in agreement with previous studies.\textsuperscript{13,14} The sharpness of the G and 2D peaks, as well as the absence of the disorder-induced D peak at $\approx 1360$ cm$^{-1}$\textsuperscript{9,10,24} D' peak at $\approx 2950$ cm$^{-1}$, shows that the samples under study are of very high quality, and the amount of disorder is negligible. However, after x-ray exposure, the Raman spectra show significant changes in all the exfoliated samples, although the degree of change decreases from single-layer to trilayer graphene and almost disappear for graphite, in line with the absorption results previously discussed. More specifically, we observe the appearance of a huge D peak at 1360 cm$^{-1}$, as well as the appearance of D' peak at 1620 cm$^{-1}$ and D'' peak at $\approx 2950$ cm$^{-1}$. These changes are accompanied by the broadening of both the G (1570 cm$^{-1}$) and 2D (2700 cm$^{-1}$) peaks. In line with the absorption results (see Fig. 2), the comparison between graphene samples with different thickness suggests that the largest radiation-induced changes occur on the single-layer exfoliated graphene sample. On the contrary, the Raman spectrum for the single-layer epitaxial graphene shows negligible change, although it has been exposed to x-ray for a much longer time ($\approx 10$ h), once again pointing to the different nature between exfoliated and epitaxial graphene, and a better stability of the latter to x-ray irradiation.

The results presented here point to a scenario where the x-rays locally break the sp$^2$ bonding giving rise to small crystallites within the same graphene sheet. This is supported by: (1) the decrease, or in some cases even the disappearance, in the $\sigma^*$-orbital-related signal in the absorption spectra (Fig. 2), suggesting a decrease in sp$^2$ bonded carbon atoms; (2) the appearance of a broad pre-edge feature [inset of Fig. 2(a)] in the absorption spectra, similar to that observed in nanographite edges;\textsuperscript{22} (3) the appearance of strong D, D' peaks in the Raman spectra (Fig. 3), associated with an increase of broken carbon bonds and edges states;\textsuperscript{9,10,14,24,25} and (4) the broadening of the G and 2D peak in the Raman spectra, suggestive of phonon confinement. The average crystallite size estimated from the ratio between the G and D peaks in the Raman spectra\textsuperscript{10} changes from 7 nm in single-layer exfoliated graphene to 10 and 12 nm in bilayer and trilayer exfoliated graphene, respectively, pointing to a smaller irradiation induced bond-breaking effect in thicker exfoliated graphene samples.

There are a few possibilities about the bond-breaking mechanism, and further investigation is needed to pin down the exact mechanism. First, the higher probability of bond breaking by x-rays in insulating samples\textsuperscript{26} suggests that the bond breaking in graphene, which is a semimetal, might be caused by the ejection of electrons into the vacuum and the

**Fig. 2.** (Color online) Time dependence of the C 1s XAS for (a) single-layer (b) bilayer, and (c) trilayer exfoliated graphene (d) exfoliated graphite and (e) epitaxial single-layer graphene. The spectra are offset to have zero intensity in the pre-edge and normalized to the same value at 315 eV for each sample. The inset in panel a shows an extreme sample which has negligible $\sigma^*$ signal (pointed to by the gray arrow) after irradiation and additional pre-edge peak (pointed to by the red arrow) which is likely associated with edge states.

**Fig. 3.** (Color online) Raman spectra for exfoliated samples with different sample thickness (1, 2, and 3 ML and graphite) and single-layer epitaxial graphene with laser excitation wavelength of 514 nm in the energy range near the D (a) and 2D peak (b). The solid and the dotted curves are taken before and after x-ray irradiation. The spectra are normalized to have the same amplitude for the G peak and 2D peak.
in insufficient restoration of the ejected electrons as a result of its low charge carrier concentration. This is particularly so considering that the SiO$_2$ layer underneath the graphene sample is quite insulating as well. Another possibility is that in exfoliated graphene, the SiO$_2$ substrate or even residual sample is quite insulating as well. Another possibility is that we have detected a very similar amount of samples partially suspended on a few

In summary, we found that single-layer exfoliated graphene is unstable under soft x-ray exposure, resulting in local breaking of the sp$^2$ bonding and the formation of small crystallites within the sample. As the interaction along the third dimension increases, either by increasing the sample thickness or through stronger bonding with the substrate, as in the case of epitaxial graphene, the graphene sample becomes more stable. These results point to the crucial role of the interaction along the third dimension in stabilizing quasi-two-dimensional graphene. Finally, this ability to easily break the carbon-carbon bonds suggests the possibility of using x-rays or even lasers$^{27}$ to “write” graphene nanostructures, an alternative to standard writing techniques. Further studies are needed to investigate where the bonds break$^{28}$ and to achieve a fine control of the amount of broken bonds.

We thank D.-H. Lee, A. K. Geim, and A. C. Ferrari for useful discussions. The photoemission and Raman measurements were supported by the Division of Materials Sciences and Engineering, Office of Basic Energy Sciences of the U.S. Department of Energy under Contract No. DE-AC03-76SF00098. A.Z. and C.O.G. acknowledge the DOE (Grant No. DE-AC02-05CH11231) for sample preparation and Raman characterization.
